Over the past years our group has been working on a coherent research program on the relationships between greenspace and health. The main aims of this “Vitamin G” program (where G stands for green) were to empirically verify relationships between greenspace in residential areas and health and to gain insight into mechanisms explaining these relationships. In this article, we bring together key results of our program regarding the relevance of three possible mechanisms: stress reduction, physical activity, and social cohesion. The program consisted of three projects in which relationships between greenspace and health were studied at national, urban, and local scales. We used a mixed-method approach, including secondary analysis, survey data, observations, and an experiment. The results confirmed that quantity as well as quality of greenspace in residential areas were positively related to health. These relationships could be (partly) explained by the fact that residents of greener areas experienced less stress and more social cohesion. In general, residents of greener areas did not engage in more physical activity. The article concludes with a discussion of the practical implications of these findings and identification of areas that need more in-depth research.

The idea that greenspace in the residential environment can promote health has a long history in environmental planning (Hartig et al. 2011). A notable example is Howard’s ([1902] 1946) *Garden Cities of Tomorrow*. The author pleaded that the advantages of town and countryside should be integrated in garden cities with optimal opportunities for health and well-being. In practice,

however, it has been difficult to realize this vision. Due to large-scale demands for housing and other services, urban greenspace has increasingly come under threat. What are the consequences of these developments for public health? Does a green residential environment indeed promote health? If so, why? The relationship between greenspace and health has only recently become a theme for empirical research (Hartig et al. 2011; De Vries et al. 2011). Prior to the Vitamin G project, only two epidemiological studies had investigated the direct relationship between greenspace and health (Takano, Nakamura, and Watanabe 2002; De Vries et al. 2003). These studies suggested a positive link between the amount of greenspace in the residential environment and health but also raised questions about the strength and robustness of this relation and the mechanisms behind it.

POSSIBLE MECHANISMS BEHIND THE GREENSPACE–HEALTH RELATIONSHIP

Three mechanisms—stress reduction, physical activity, and social cohesion—are frequently mentioned in the literature. They are well-known predictors of health (U.S. Department of Health and Human Services 1996) and might also be related to the availability of greenspace.

Stress Reduction

Many people consider contact with nature one of the most powerful ways to obtain relief from stress and mental fatigue (Grahn and Stigsdotter 2003). This mechanism can be regarded as a remnant of evolution in natural environments, during which humans have developed a partly genetic readiness to respond positively to unthreatening natural settings that were favorable to well-being and survival (Ulrich 1993).

Natural scenes seem to have a unique attention-drawing quality (soft fascination; Berto, Massaccesi, and Pasini 2008), which repletes directed attention and replaces negative emotions (S. Kaplan 1995). Evidence for these restorative responses has been collected through field studies in such diverse settings as wilderness areas (Hartig, Mang, and Evans 1991) and gardens (Ottosson and Grahn 2005). Even viewing nature from the window of one's home can provide "micro-restorative" opportunities that can build resilience against stress (R. Kaplan 2001). Viewing slides or videos of natural environments leads to a faster and more complete stress recovery than viewing built environments (Ulrich et al.

1991; Van den Berg, Koole, and Van der Wulp 2003).

In sum, there is substantial evidence that restoration from stress and mental fatigue is a potentially important mechanism in the relationship between greenspace and health.

Physical Exercise

People more easily undertake physical activities, such as cycling and walking, in aesthetically appealing environments (Pikora et al. 2003; Owen et al. 2004), perhaps even for longer periods of time (Pretty et al. 2007). The evidence for a positive influence of greenspace on physical activities, however, is as yet mixed and inconclusive (positive: Ellaway, Macintyre, and Bonnefoy 2005; McGinn et al. 2007; no relation: Hoehner et al. 2005; Hillsdon et al. 2006; McGinn et al. 2007; negative: Duncan and Mummery 2005).

Apart from differences in the geographic context of studies, this mixed evidence might be related to the intrinsic character of the motivation to exercise. People who

want to be active will find themselves a way to do so, even if it requires taking the car to travel to a faraway green area. Moreover, some greenspaces invite passive forms of recreation rather than active forms.

Thus, although intuitively plausible, the literature suggests that physical activity is not a strong candidate for explaining the relationship between greenspace and health.

Social Cohesion

Meeting opportunities are important for social ties with neighbors, leading to more cohesive communities (Volker, Flap, and Lindenberg 2007). The presence of green in common spaces might attract residents to outdoor spaces, leading to more frequent contacts (Coley, Kuo, and Sullivan 1997). Studies in an underprivileged area of Chicago provide indications for a positive relation between green public facilities and social ties (Kuo, Sullivan, and Wiley 1998; Kweon, Sullivan, and Wiley 1998). Besides offering meeting opportunities, greenspace can promote a general sense of community, which might decrease feelings of loneliness and increase social support (Prezza et al. 2001). Overall, there are several indications for social cohesion as a possible mechanism underlying the relation between greenspace and health.

Against this background, the Vitamin G program aimed to empirically verify a positive relationship between greenspace in the residential environment and health and to evaluate the importance of the three mechanisms mentioned. In the remainder of this article, we first briefly describe the study method, followed by an overview of the main findings. In this overview, we bring together the findings regarding the relevance of the three explanatory mechanisms (stress reduction, physical activity, and social cohesion).

STUDY DESIGN, DATA, AND METHODS

The Vitamin G research program consisted of three projects, each with a different scope (Groenewegen et al. 2006). The first project had a national scope and used data from The Netherlands as a whole. The second project focused on eighty neighborhoods in four Dutch cities (urban scale). The third project studied allotment gardens in and around twelve Dutch cities (local scale).

In each project, greenspace indicators were linked to health indicators. All analyses were carried out at the level of individuals, and multilevel analysis was used to control for the nesting of individuals in neighborhoods wherever necessary. The analyses were controlled for characteristics known to be associated with health (e.g., age, gender, education, income, urbanity). Given the egalitarian health care system and the high density of health service provision in The Netherlands, there was no need to add additional variables regarding access to health care. In the national study, greenspace around people's homes was related to subjective and objective health. Land use data were derived from the National Land Cover Classification database and aggregated to the percentage of greenspace in circles with a 1- and 3-km radius around the six-digit postal code of the respondents' addresses. Health data were derived from the second Dutch National Survey of General Practice (Westert et al. 2005). This was a two-stage sample of 104 family practices, a one-page mailed questionnaire among the practice population of approximately 400,000 people (in The Netherlands, virtually the whole population is registered with a practice), 300,000 respondents (76%), and health interviews among a random sample of the practice population, resulting in 12,700 respondents (64%). Objective health data were derived from electronic medical records of the practice populations.

The urban neighborhood study related quantity and quality of greenspace to self-reported health. Data on health and explanatory variables (related to stress, physical activity, and social cohesion) were collected through mailed questionnaires (1,641 respondents) sent to residents of twenty neighborhoods (average size 2,200 inhabitants) in four cities. To measure the quantity of larger green areas (parks, etc.), we used land use data from Statistics Netherlands. Trained observers assessed the quality of three larger green areas as well as the amount and quality of streetscape greenery (not captured in the land use data) at four preselected points within each neighborhood. Quality indicators encompassed accessibility, maintenance, variation, naturalness, colorfulness, clear arrangement, shelter, absence of litter, safety, and general impression.

The allotment garden study involved a comparison of gardeners and their neighbors with no allotment. The study consisted of a survey among members of twelve allotment sites (121 respondents) and a control group of their neighbors without an allotment (63 respondents).

The survey included self-reported health and measures of stress, physical activity, and social cohesion.

A distinction was made between respondents younger or older than sixty-two. In addition to the survey, a field experiment among thirty allotment gardeners was conducted. The gardeners first performed a stressful task and were then randomly assigned to thirty minutes of gardening or indoor reading. Salivary cortisol levels and self-reported mood were repeatedly measured before and after the stressful task and during and after the restorative activity.

RESULTS

Greenspace and Health

The national study showed that residents of greener areas felt healthier than residents of less green areas (Maas et al. 2006; see Figure 1). Furthermore, for fifteen out of twenty-four physician-assessed morbidity clusters, the incidence rates were negatively related to the amount of greenspace within a 1-km radius around people's homes (Maas, Verheij, et al. 2009). The relationship was strongest for anxiety disorders and depression; for depression the chances were 1.33 times higher in areas with little greenspace than in areas with very much greenspace. Across different studies, relationships between greenspace and health tended to be stronger for individuals of a lower socioeconomic status (SES), younger age groups, and the elderly.

In the urban neighborhood study, both the quantity and quality of nearby green areas and streetscape greenery were positively related to self-rated health, number of acute complaints, and mental health status (Van Dillen et al. 2011).

In the allotment garden study, gardeners sixty-two years and older scored significantly better than their neighbors on physical disabilities, health complaints, and family physician consultations and marginally better on perceived general health and chronic illness than their neighbors in the same age category (Van den Berg, Van Winsum-Westra, et al. 2010).

[FIGURE 1]

Stress Reduction

The national study investigated the extent to which greenspace can buffer adverse health impacts of stressful life events (Van den Berg, Maas, et al. 2010).

Detrimental impacts of stressful life events on perceived general and acute health complaints were less strong for respondents with much greenspace in a 3-km radius around their home than for respondents with little greenspace in a 3-km radius (Figure 2). The same pattern was observed for perceived mental health, although it was marginally significant.

In the urban neighborhood study, stress turned out to be a full mediator of the relationship between the quantity of streetscape greenery and mental health and a partial mediator of the relationships with self-rated health and number of acute health complaints. Stress explained one fifth to over two fifths of the relationships of quantity of streetscape greenery with these health indicators (Figure 3). In the relationships of health indicators with quality of streetscape greenery, stress was always a partial mediator (De Vries et al. forthcoming).

In the allotment gardening survey, 86 percent of the gardeners reported feeling less stressed after a visit to their allotment garden; 56 percent rated stress relief as a very important reason for gardening (Van den Berg, Van Winsum-Westra, et al. 2010). Older allotment gardeners had experienced less stress recently and seemed better able to cope with stress. The field experiment showed that gardening led to stronger decreases in the stress hormone cortisol than reading (Van den Berg and Custers 2011).

Physical Activity

[FIGURE 2]

At the national scale no relationships were found between the amount of greenspace in the area and time spent on physical activity in general, sports, and walking for commuting purposes (Maas et al. 2008). For walking and cycling in leisure time, residents of areas with much greenspace spent even less time on these activities than residents of areas with little greenspace. Greenspace and cycling for commuting purposes were positively related, but this could not explain the relationship between greenspace and health.

The urban neighborhood study also indicated that total physical activity could not explain the relationship between greenspace and health, as it was not related to greenspace (De Vries et al. forthcoming). Only “green” physical activities (activities that could be undertaken in the public space of the neighborhood, such as walking and cycling) were related to greenspace but to a lesser extent than stress. In all analyses, green physical activity was at best a partial mediator of the relationships between quantity and quality of streetscape greenery and the self-reported health indicators. Green physical activity explained less than 10 percent of the direct relationships of quantity of streetscape greenery with the health indicators (Figure 3). [figure3] In the allotment gardening study, 50 percent of gardeners found staying active very important for having an allotment garden (Van den Berg, Van Winsum-Westra, et al. 2010). Younger and older allotment gardeners had better scores on physical activity than the control group.

In summer, 84 percent of the allotment gardeners met the Dutch public health recommendations for physical activity compared to only 62 percent of the control group.

Social Cohesion

The national study showed that residents with a high amount of greenspace in their residential environment felt less lonely and less often experienced a shortage of social support than residents with a low amount of greenspace in their residential environment (Maas, Van Dillen, et al. 2009). The amount of greenspace was not related to the actual frequency of contact with neighbors or the number of supportive interactions. All relationships between greenspace and self-reported health, number of health complaints, and mental health were at least partially mediated by loneliness and shortage of social support. The relationship between greenspace and mental health could even be fully explained by the fact that residents of greener areas less often experienced a shortage of social support.

In the urban neighborhood study, the finding that residents of neighborhoods with higher amounts of streetscape greenery reported less acute health complaints and better mental health could be fully explained by the stronger social cohesion in greener neighborhoods.

Social cohesion also partly explained the positive relationship between quantity of streetscape scenery and self-rated general health. Overall, social cohesion explained one fifth to one third of the relationships between quantity of streetscape greenery and the health indicators (see Figure 3). Furthermore, social cohesion was always a partial mediator in the analyses of the relationships of health indicators with the quality of streetscape greenery (De Vries et al. forthcoming).

Only 17 percent of allotment gardeners mentioned social contacts as a very important motive for gardening (Van den Berg, Van Winsum-Westra, et al. 2010). Nevertheless, older gardeners felt significantly less lonely than neighbors in the same age group, and they also reported having marginally more social contacts with friends.

DISCUSSION

This article has provided a summary of the results of the Vitamin G research program, with an emphasis on the mechanisms behind the relationship between greenspace and health. The studies within the program provide converging evidence for a positive relationship between greenspace in the residential environment and health, using different self-reported and objective greenspace and health indicators. Stress reduction and social cohesion were found to be the most important mechanisms.

The relationships between greenspace and health are consistent with other epidemiological studies conducted in England (Mitchell and Popham 2007), Denmark (Nielsen and Hansen 2007), and Sweden (Björk et al. 2008). However, a recent study in New Zealand found no relationship between greenspace and mortality (Richardson et al. 2010). The authors explained this in terms of diminishing marginal returns at the large amount of greenspace, characteristic for New Zealand residential neighborhoods.

Greenspace was found to be especially important for mental health. In the national study that used physician-assessed morbidity, the strongest relationships were found for anxiety disorders and depression.

This is in line with findings from previous studies that have also consistently reported stronger positive impacts of contact with greenspace on mental than on physical health (e.g., Sugiyama et al. 2008).

Also consistent with previous research (e.g., Mitchell and Popham 2008), the overall results suggest that people with lower SES, younger people, and the elderly benefit more from green areas in their residential environment.

Although exposure to greenspace was not measured, these findings might be tentatively explained by the fact that these groups spend more time in the vicinity of their homes and thus are more exposed to characteristics of their residential environment. Moreover, those who spend less time in the residential environment might be additionally affected by a lack of greenspace as is typical for many work environments (Kwan 2009).

The mediation analyses in the neighborhood study suggest that stress reduction and social cohesion, in that order, are the most important mechanisms in explaining the relationship between greenspace and health. These findings are consistent with findings of previous research that have consistently shown strong links between greenspace and stress and social cohesion and only weak and mixed evidence for links between greenspace and physical activity. Few studies, however, have directly tested mediational models. As a notable exception, a survey in Australia showed that recreational walking could fully explain the link between greenness and physical health, whereas the relationship between greenness and mental health was partly accounted for by recreational walking and social cohesion (Sugiyama et al. 2008). These results are consistent with the finding in the Vitamin G program that social cohesion is an important mediator of greenspace–health relationships. The findings of the Vitamin G program with respect to the mediational role of physical activities (e.g., recreational walking) were more mixed and inconclusive, however.

STRENGTHS AND LIMITATIONS

Contrary to many other studies, the Vitamin G program encompassed different geographical scales and levels of urbanity, taking into account different subjective as well as objective health indicators and various indicators of greenspace. Most of the Vitamin G studies also used large data sets and state-of-the-art statistical (multilevel and mediational) analyses. Same-source bias was avoided by using objective indicators for greenspace along with observations. These aspects contribute to the validity and practical applicability of the results.

The most important limitations relate to exposure and causality, probably the two most difficult issues to address in studies of environment and health. The length and intensity of residents' exposure to green elements was not directly measured. With regard to causality, selection cannot be ruled out as an alternative explanation for our results but can only be made less plausible by using adequate control variables in the analyses.

Other limitations include the fact that we investigated only three mechanisms, although there are several other possible candidates (e.g., connectedness to nature, increased vitality; cf. Hartig et al. 2011). Furthermore, we have only looked at relatively nearby greenspace. For some purposes, people might seek out more distant areas. Moreover, our studies were done in a densely populated country with very little (wild) nature. As a consequence, the importance of nearby greenspace for

health might have been overestimated as compared to other countries with more abundant nature (Richardson et al. 2010).

Future Research and Practical Implications

Future research should address these limitations.

Better measurements of exposure are possible through Global Positioning System (GPS) measurements, as already used in transport geography. Using such measurements could provide detailed information on the time people spend in particular environments during daily activities (Kwan 2009). Direct selection effects can be ruled out with longitudinal studies, which include geocoded information. With respect to implications for spatial planning and public health, it is important to study in more detail which aspects of greenspace are related to which mechanisms and which health outcomes. An important general guideline that can be derived from the Vitamin G program is that the quality of urban greenspace, besides quantity, has an additional beneficial effect on health.

Proximity (comparing distances of 1 and 3 km) did not make much difference for self-rated health, but nearby green areas seem to be more important for physician-assessed morbidity, whereas less proximate areas seem to be more important for buffering stress. Moreover, we still do not know much about the relative contribution of greenspace compared to other environmental characteristics, both socioeconomic and physical.

More insight is also needed in possible international variation in the greenspace–health relationship.

Research in northwestern Europe indicates that the relationship exists, irrespective of large differences in population density and types of greenspace, but as greenspace might affect different individuals in different ways, more attention to the interaction between individuals and their environment is required.

By answering these questions, future research could provide a fuller understanding of the intricacies of the greenspace–health relationship and help to design effective and health-promoting greenspace policies.

FIGURES

Figure 1. Estimated relationship between amount of greenspace (in a 3-km radius) and self-perceived health (percentage stating that their health is less than good) based on a logistic multilevel model controlling for age, gender, income, education, and urbanity (taken from Maas et al. 2006). (Color figure available online.)

Figure 2. Estimated marginal means of perceived general health (1 = excellent; 5 = poor) as a function of stressful life events in past three months (white bars: no life events; black bars: life event(s)) and amount of greenspace in a 1-km and 3-km radius, controlling for age, gender, income, education, and of urbanity (taken from Van den Berg, Maas et al. 2010).

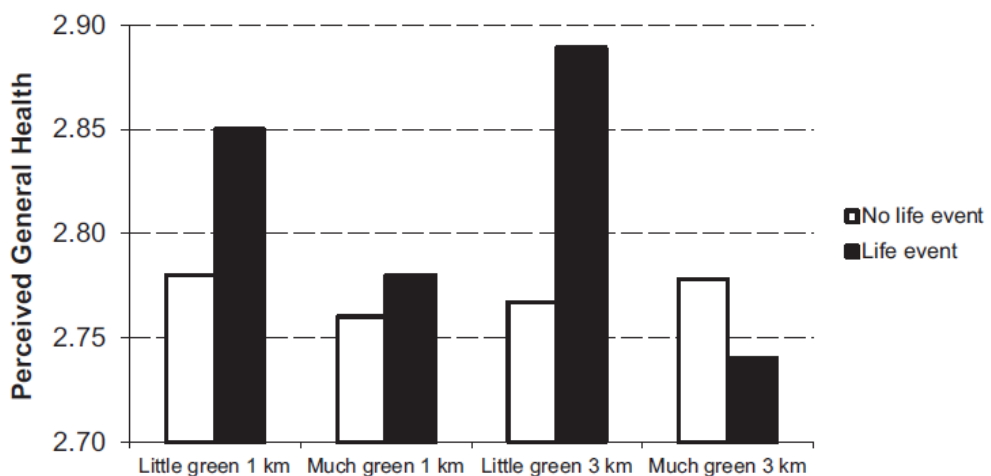

Figure 3. Indirect effect on health indicators as percentage of total effect of quantity of streetscape greenery for the three mediators separately and combined, controlling for gender, age, education, income, life events, having children living at home, smoking, and excessive drinking (taken from De Vries et al. forthcoming). PA = physical activity. (Color figure available online.)

Mediated part of effect for quantity (%)

■ Stress ■ Cohesion ■ Green PA ■ All three
